Abstract: Air pollution has inevitably come along with the economic development of human society. It has been a global concern that how to balance economic growth with sustainable environment. The ambient PM$_{2.5}$ (particulate matter with aerodynamic diameter ≤ 2.5 μm) is particularly life-threatening because these tiny aerosols could be inhaled into human respiration system and cause millions of premature deaths every year. The focus of most relevant researches has been placed on apportionment of pollutants and the forecast of PM$_{2.5}$ concentration measures. However, the spatiotemporal variations of pollution regions and their relationships to the local factors are not much contemplated in the literature. These local factors include at least land terrains, meteorological conditions, and anthropogenic activities. In this paper, we propose an interactive analysis platform for spatiotemporal retrieval and feature analysis of air pollution episodes. The domain expert can interact with the platform by specifying the episode analysis intention considering various local factors to reach his/her analysis goals. The analysis platform consists of two main components. The first component offers a query-by-sketch function where the domain expert can search similar pollution episodes by sketching the spatial relationship between the pollution regions and the land objects. The second component helps the domain expert choose a retrieved episode to conduct spatiotemporal feature analysis in a time span. The integrated platform automatically searches the episodes most resembling to the domain expert’s original sketch and detects when and where the episode emerges and diminishes. These functions are helpful for domain experts to infer insights how the local factors result in particular pollution episodes.

Keywords: PM$_{2.5}$; Pollution episode; Spatiotemporal analysis; Query-by-sketch; Feature detection

1. Introduction
Air pollution reduction has been the core solution to facilitate several Sustainable Development Goals (SDGs) such as sustainable cities and communities, responsible consumption and production, and climate action [1]. The conflict between air pollution reduction and economic growth needs to be resolved by establishing a comprehensive model for describing the pollution life cycle [2]. However, the focus of existing research has been placed on pollution apportionment and PM$_{2.5}$ concentration forecast. The analysis for the patterns of emerging pollutions and the variations of PM$_{2.5}$ concentration at different places and times has been overlooked in the literature [3]. It is thus critical to develop a spatiotemporal analysis platform where the user can be positively involved in the process and able to express the intention to reach his/her analysis goals. This kind of user-interactive platform is very useful to generate insightful implications by combining the knowledge of domain experts and the lore of artificial intelligence.

Modelling for PM$_{2.5}$ concentrations is a challenging task because we need to apportion the sources which emit the aerosols and analyze the transportation pathways the aerosols flow. The PM$_{2.5}$ sources could be generated from nature (dust soiling, volcanic eruptions, sea salt, etc.), anthropogenic activities (vehicle emissions, burning activities, coal and gasoline combustion, etc.), or photochemical transformation of precursor emissions such as sulfur dioxide (SO$_2$) and nitrogen oxides (NO$_x$). Several models of PM$_{2.5}$ source apportionment have been proposed. The most prevalent ones are the receptor model and the tracer model. The receptor model stems on the principle of pollutant’s mass conservation stipulating that the measured density of a pollutant element is conforming to that for all nearby sources that contain the pollutant element [14-25]. The tracer model, on the other hand, directly captures pollutant samples at potential sources and analyzes the chemical characteristics of the samples. By using the metal elements and ions as tracers or markers, the tracer model can induce an evidence for the sources contributing to the PM$_{2.5}$ compositions [26].

Both the receptor model and the tracer model require expensive particulate sensors to identify the element in the captured pollutants. Government agent can only afford to establish air quality monitoring supersites at hot-spot places such as industrial complex or metropolis. However, the pollution sources could happen anywhere and anytime. Moreover, the transportation of the emitted particulates is influenced by the cyclone conditions and geographical landscape which are also location- and time-dependent [17]. Hence, spatial, temporal and spatiotemporal analyses are critical for developing a robust and reliable model of explaining the PM$_{2.5}$ pollution episodes. Thanks to the government-executed Digital Construction Design Project for construction of the Internet-of-Things (IoT) of low-cost sensors, more than 9,600 microsites have been set up nation-wide as of June 20, 2023 (see Figure 1). Although the low-cost sensor IoT cannot work with the receptor model or the tracer model to identify the chemical elements contained in the pollution, it does open a door for conducting spatiotemporal pollution analysis with fruitful image analysis techniques.

In this paper, we propose a visualization-based spatiotemporal analysis approach which enables the user to actively specify the spatial relationships between pollution objects and land objects to retrieve most similar pollution episodes observed in history. The user can click on a retrieved episode and call up a pollution feature detection function to further examine the spatiotemporal characteristics of the pollution features. Our analysis method is novel in terms of not only offering a visualization platform for analyzing pollution episodes but also saving a lot of human efforts to search and extract...
the pollution features from the big volume of monitored air-quality data.

Figure 1. Air quality IoT of low-cost sensors (image from Taiwan EPA, https://wot.epa.gov.tw/).

The remainder of this paper is organized as follows. Section 2 reviews the relevant research on air-pollution spatiotemporal analysis and the image analysis techniques which are related to our proposed methodologies. In Section 3, the spatiotemporal analysis framework is proposed and the offered analysis functions are elucidated. Section 4 presents the experimental results with illustrative examples. Finally, Section 5 concludes this work.

2. Literature review

2.1. Spatiotemporal pollution analysis

The spatial pollution analysis intends to disclose the changes of variation or relationship between pollution concentration over different places, while the focus of temporal pollution analysis is on changes over different times. The spatiotemporal pollution analysis models the pollution changing dynamics over both space and time dimensions, proposing a more challenging task than that performed on either space or time domain individually. The characteristics of existing literature can be compared according to the methodologies applied to the spatiotemporal analysis. From our literature review, the articles of spatiotemporal pollution analysis mainly adopt five approaches, as chronicled in Table 1.

The first type of approaches is probability based. Probability distributions are employed to model the spatiotemporal variations of PM$_{2.5}$ concentrations. Both parametric and non-parametric probability distributions can be used depending on the merit of approximation. It is assumed in Yu and Wang [48] the PM$_{2.5}$/PM$_{10}$ ratio is invariant at the same location during the same period of a year. They used the
historical data of PM$_{2.5}$/PM$_{10}$ ratios to construct a non-parametric probability distribution for predicting PM$_{2.5}$ given the PM$_{10}$ concentration. Jiang et al. [9] applied a parametric probability distribution which used two parameters to describe the shape and the phase characteristics of the probability density functions (PDFs) of the hourly PM$_{2.5}$ concentrations in each city over seasonal time frames. The optimal value of the two parameters are determined by fitting the historical data. The number of articles applying probability-based approaches is small as compared to that using other approaches. The reason is due to the difficulty for explaining the result of probability distributions.

PM$_{2.5}$ given the PM$_{10}$ concentration. Jiang et al. [5] applied a parametric probability distribution which used two parameters to describe the shape and the phase characteristics of the probability density functions (PDFs) of the hourly PM$_{2.5}$ concentrations in each city over seasonal time frames. The optimal value of the two parameters are determined by fitting the historical data. The number of articles applying probability-based approaches is small as compared to that using other approaches. The reason is due to the difficulty for explaining the result of probability distributions. Classic statistics is a more popular approach in early researches. In particular, the correlation coefficient (CC) and coefficient of variance (CV) are broadly employed statistic indices for conducting spatiotemporal analysis between air pollutants monitored at different sites along a given time span. The spatiotemporal

Mathematical Biosciences and Engineering
distribution of air pollution characteristics in Jiangsu Province, China is studied in Song et al. [106], which elaborately examined the spatial and temporal CC between air quality index and meteorology, and between major pollutants variations. Dai et al. [7] calculated CV among different sites within a city. A higher CV indicates a greater fluctuation of PM2.5 concentrations in a city. Moreover, Dai et al. [7] calculated the Theil index to estimate the regional variations in PM2.5 of different sites among multiple cities. Lung et al. [118] disclosed that the CV among ten community locations exceeds 20% in more than one-fifth of the days in July and December. The largest variations typically appear on weekends, mainly yielded by traffic, restaurants, and temples. Lung et al. [118] also investigated the CC between microsites and the nearest supersite to validate the consistence of pollution patterns at highly correlated sites. Yang et al. [129] investigated the CC between PM2.5 concentrations/variations and the urbanization level of the city. Their result manifests there was a positive/negative correlation between urbanization and PM2.5 concentrations/variations.

The third group of articles stick to the regression methodology. The regression technique is useful in finding the relationship between a set of independent variables and the responsive variable. Regression has been applied to estimate the pollution concentrations from meteorological or socioeconomic factors. Habermann et al. [130] chose five independent factors, namely, the altitude, distance to industrial land use, distance to expressways, traffic flow, and demographic. They applied linear regression to model NO2 concentration in these factors. Similarly, Lung et al. [118] and Liu et al. [141] applied spatial linear regression on neighboring monitoring sites and economic variables in a particular time period. Yang et al. [129] used spatial regression with a quadratic expression to disclose the contribution of urbanization, industrialization, and green land area, to the accumulation of PM2.5 concentrations. The next category of articles applied time series analysis to find the trend of PM2.5 concentrations and related factors, such as atmospheric conditions, land observations, human activities, and diseases. Wei et al. [12] conducted a time-series analysis approach to explore the effect of short-term ambient ozone exposure on hospitalization due to acute myocardial infarction. The recommendations for relevant public health policies were made based on the quantified number of related hospitalizations and costs. Liu et al. [13] acquired the concentration data of PM2.5, PM10, SO2, NO2 and O3 during 2014–2022 at fourteen monitoring sites across Shanghai and it is seen from the results of time series analysis that the concentrations of observed pollutants except O3 and NO2 were decreased in trend at all sites. Dzhambov et al. [154] aimed to investigate the short-term effects of air pollution on hospital admission for asthma in Sofia during the period of January 1, 2009 to December 31, 2018. Negative binomial regressions were analyzed to disclose associations between air pollution and daily hospital admission for asthma.

More recently, machine learning approaches emerge as prevailing methods for air pollution spatiotemporal analysis. Yan et al. [15] used a spatially adjacent matrix and the PM2.5 concentrations tallied by all the monitoring sites in 13 cities of the Beijing-Tianjin-Hebei (BTH) region to conduct a spatial clustering analysis. Their study showed that the PM2.5 spatial homogeneity is the highest in winter and the lowest in summer, and for the same time period the PM2.5 spatial variations increase from southeast to northwest of the BTH region. Cao et al. [16] considered the hourly PM2.5 concentrations in each day as a 24-dimension vector, and applied the agglomerative hierarchical clustering approach to partition the PM2.5 time series into four groups. They identified that the first group contains those days with severe pollution, the second group corresponds to the dispersion period,
the third group coincides with the pollution accumulation period, while the air is relatively clean during the days included in the last group. Cao et al. [16] further applied the entropy weight method (EWM) to calculate the weighted mean PM$_{2.5}$ of the four clusters for each monitoring site in the city, where the cluster weight is given by the reciprocal entropy. The weighted mean PM$_{2.5}$ can be used to identify the PM$_{2.5}$ hotspots in the city. Lyu et al. [17] systematically examined the spatiotemporal variations of air pollutants in the BTH region and then applied the random forest model and the decision tree regression for predicting spatiotemporal variations of pollution concentrations. It is found that the importance of factors influencing the prediction performance depends on the spatial trend of variations. In Zareba et al. [18], unsupervised clustering algorithms were applied to analyze spatiotemporal patterns of air pollution in Krakow, Poland, over one-year hourly PM$_{10}$ data. It revealed that the “bagel” pattern is found in the case of maximum concentrations, due to pollutions produced in Krakow’s surrounding counties and the city of Krakow form a separate cluster. For the case of average concentrations, Krakow city and its southeastern counties were grouped in one cluster, separating from the northwest part, due to the topography of terrain.

More recently, several advanced studies have been conducted in various countries, such as the United States, Poland, South Korea, and Japan. These studies applied hybrid or machine learning approaches to boost the performance of prevailing methods for air-pollution spatiotemporal analysis. In the United States [16-17], hybridized statistics, regression, and time-series analysis to disclose the relationship between air pollution and public health. A spatiotemporal interpolation and visualization of real-time air pollution data for the contiguous United States is also provided. For the study conducted in Krakow, Poland [18], unsupervised clustering algorithms were applied to analyze spatiotemporal patterns of air pollution in Krakow, Poland, over one-year hourly PM$_{10}$ data. It revealed that the “bagel” pattern is found in the case of maximum concentrations, due to pollutions produced in Krakow’s surrounding counties and the city of Krakow form a separate cluster. For the case of average concentrations, Krakow city and its southeastern counties were grouped in one cluster, separating from the northwest part, due to the topography of terrain. The study in Seoul, South Korea [19] showed that 64.9% of the premature mortality cases in 2019 are due to PM$_{2.5}$, while the remaining are attributed to NO$_2$. The study integrates random forest approach into land-use regression modeling to predict daily and diurnal PM$_{2.5}$ and NO$_2$ in Seoul, South Korea, and evaluate the significance of contributing factors to premature mortalities. It was found that in 2019, 64.9% of the relevant cases are due to PM$_{2.5}$, while the remaining are attributed to NO$_2$. Chicas et al. Finally, in the study at Nagasaki Prefecture, Japan [20], proposed a hybrid method which combines statistical correlation, time series analysis, and machine learning techniques to make the interpretation of the pollution dynamics more complete. The method study offers a holistic perspective about the pollution dynamics.

Most of the existing methods conduct analyses separately on spatial or temporal domain due to the high complexity of computations incurred by enormous combinations in spatiotemporal scenarios. However, the higher-level correlation existing in the spatiotemporal domain can only be disclosed from...
a holistic view on both dimensions. The classic approaches relying on probability, statistics, and regression, whose numerical results are hard to interpret and lacking a visualization facility to deliver the implications. In this paper, we propose to use image processing techniques to facilitate air-pollution spatiotemporal analysis. The benefits of our method is two-fold. Firstly, the analysis result obtained by applying image processing technique is visualizable and is intrinsic to interpret the implications. People prefer to see images rather than numeric values to infer insightful knowledge. Secondly, image processing is a well-established discipline and there exist many available algorithms for elaborate analyses.

2.2.1.2. Spatial image retrieval

Most image retrieval methods focus on similarity matching between image features, such as with colors, textures, and contours, without paying too many attentions at the spatial relationship between the objects in the image. However, in the applications of some domains such as the geographic information system and urban planning, the object spatial relationship is particularly important. There is a need for a methodology to describe the spatial relationship, for example, “the park to the west of the city hall” or “the fire station contained in the district”. To this end, Chang et al. [21] proposed the 2D string data structure which tallies the sequence of object projections along the $x$ and $y$ axes, respectively. Figure 2 shows an example of the 2D string for an image whose objects have been represented by alphabetical symbols. The 2D string containing the projection sequence of the objects along the $x$ and $y$ axes is $(A = D:E < B < C = F, A = B < C < D:E = F)$, where the indicator “<” denotes “left of” for the $x$ projection sequence or “below” for the $y$ projection sequence, the separator “=” means “at the same location along the referred axis”, and the indicator “:” corresponds to “at the same location along both axes”.

![Figure 2. An example of the 2D string.](image)

However, the 2D string has application limitations. The objects have to be constrained in grids and the 2D string cannot describe complex spatial relationships between objects such as “contained” and “overlapped”. Many improved versions of the 2D string exist. A notable one is the 2D Be-string [22] which removes all of the indicators and is hence more efficient than 2D string. The 2D Be-string representation is as follows. Every object produces two projection lines intersecting at the beginning and ending boundaries of the object along each axis. A dummy object projection line “#” is inserted between two consecutive projection lines if they are not coinciding. Figure 3 illustrates the construction of the 2D Be-string for an image containing five objects. For each of the five objects, two projection lines with the subscripts “b” and “e”, respectively, intersect the object at the beginning and ending boundaries. It is noted that a dummy object projection line “#” is placed at the beginning and the end
of the string for each axis because the objects are not aligned with the image boundaries. Therefore, the complete 2D Be-string of the image in Figure 3 is (#A_bB_b#A_e#D_b#E_b#C_e#D_e#, #B_bD_b#B_b#D_b#A_b#C_b#E_b#E_e#A_e#C_e#). It is seen in this example the 2D Be-string can describe complex spatial relationships such as "contained" and "overlapped", and the location of the objects does not have to be constrained within a grid.

Figure 3. The 2D Be-string of an iconic picture.

The next step is to estimate the similarity between two images already represented by the 2D Be-string representation scheme. Wang [22] proposed to compute the similarity based on the longest common subsequence (LCS) between the 2D Be-strings of the two images. The LCS between two strings is defined as follows. A subsequence of a string is a new string obtained by deleting some characters from it without changing the relative ordering of the remaining characters as that in the original string. The LCS of two strings is the common subsequence of them that possesses the greatest number of characters. As an example for illustration of LCS, let us consider two strings, \( S = "ACEGKI" \) and \( T = "BKCDGRI" \). Many subsequences can be created from \( S \) and \( T \) by deleting arbitrary characters from the original strings. For example, "A", "EK", "CGI", and "ACEG" are subsequences of \( S \) and "D", "CR", "BDGI", and "BKCDGRI" are subsequences of \( T \). Among the common subsequences of \( S \) and \( T \), "CGI" is the LCS that is the one which possesses the greatest number of characters among all common subsequences of two strings. Apparently, the LCS focuses on how similar the subsequences of two strings are, but ignores the differences between them. That is, longer strings tend to have longer LCS. The measure needs to be normalized by the string length.

The application of computing the 2D Be-string similarity proceeds as follows. Assume that the user submits a query image \( Q \) containing \( N \) objects, and \( Q \) is to be matched with every database image \( D \). Let the 2D Be-string representation for \( Q \) and \( D \) be \( Q = (Q_x, Q_y) \) and \( D = (D_x, D_y) \). The LCS between \( Q_x \) and \( D_x \) is derived and let it be denoted by \( C_x \), and the LCS excluding the dummy objects be denoted by \( M_x \). Let \( L(S) \) denote the function that returns the length of string \( S \). The similarity between \( Q_x \) and \( D_x \) can be derived as follows.

\[
Sim_x = \begin{cases} 
\max \left( 0, 1 - \frac{4 \cdot (L(Q_x) + L(D_x) - 2L(C_x))}{4N + 12} \right) & L(M_x) > 0 \\
0 & L(M_x) = 0
\end{cases}
\]  

(1)

 Mathematical Biosciences and Engineering
The similarity $\text{Sim}_y$ between $Q_y$ and $D_y$ can be computed similarly.

Next, we can derive the overall similarity between $Q$ and $D$ as the mean of $\text{Sim}_x$ and $\text{Sim}_y$ as calculated as follows.

$$\text{Sim} = \frac{\text{Sim}_x + \text{Sim}_y}{2} \quad (2)$$

With Eq (1) and Eq (2), one is able to compute the similarity between the query and every database image. The retrieved images are ranked in the order of decreasing value of similarity to the query.

2.3.1.3. Convolutional feature detector

There exist a bunch of convolutional feature detectors in the field of image processing and analysis. The probability of a pixel being an element of a particular feature such as a line, an edge, a corner point or an isolated point, can be estimated by examining the intensity of its neighboring pixels. Convolutional filters can be designed to estimate the feature probability. In literature, various convolutional filters have been proposed such as line detector, corner-point detector, and edge detector. We briefly review two examples in the following.

Line is a sequence of contiguous pixels which have high-contrasting intensity compared to those pixels residing at both sides. The convolutional filters as shown in Figure 4 can be applied to detect the presence of vertical, horizontal, and oblique-orientation lines in an image.

**Figure 4.** Line filters for detecting vertical, horizontal, and two oblique-orientation lines.

Edge exist at boundaries between adjacent heterogeneous regions which share the same side. Noise removal is usually preceding the edge detection process to avoid the presence of false edges. The Prewitt operator suggests the edge filters as shown in Figure 5 to detect the presence of vertical, horizontal, and oblique edges in an image. There exist other edge detectors such as Roberts operator and Sobel operator. We omit introduce these operators in the Supplement material descriptions for saving the space.

**Figure 5.** Prewitt edge filters for detecting vertical, horizontal, and two oblique edges.
These convolutional feature detectors are simple yet powerful operations which can automatically extract the air pollution features releasing important clues, such as a furnace combustion point pollution, a line emitting source of road traffic, or a large pollution region from a dust storm, resulting in different pollution episodes. Moreover, the fast computation nature of convolution operation facilitates the application of analysis on both spatial and temporal domains, overcoming the computation difficulty suffered by existing methods.

3.2 Proposed Methods

3.2.1 Framework architecture

The framework architecture of our proposed methods is shown in Figure 6. We resolve the monitored field as an \( n \times n \) image and consider the measured PM\(_{2.5}\) concentrations as the gray intensities in the image. By deploying an IoT of PM\(_{2.5}\) low-cost sensors, we are able to acquire the time series data of PM\(_{2.5}\) concentrations and corresponding air-quality alert categories. For each image in the PM\(_{2.5}\) alert time series, the connected component with the homogeneous alert category form an object in the image. Every object is labeled with a unique ID and the boundaries of its minimum bounding rectangle are recorded. The object information is used to generate the 2D Be-string representation of the image. To facilitate the pollution episode retrieval, a query-by-sketch interface is developed where the user can sketch the alert-objects of interest and the spatial relationship between them. The 2D Be-string of the query is generated and is compared to that of every database image in the alert time series. The retrieved result shows the alert database images in the order of decreasing similarity score to the query. To further explore the pollution episode, the user can click the retrieved image of interest and is led to the episode feature detection interface. Various convolutional filters can be employed to explore the changes of the detected features in the short-term PM\(_{2.5}\) concentration time series containing the episode. Our proposed methods are novel given the fact that this research is the first proposal for applying image processing techniques to facilitate the air pollution spatiotemporal analysis. The analysis result is visualizable and is intrinsic to interpret the implications.
3.2.2.2. Pollution map time series generation

In this paper, we chose Puli basin as our study field as shown in Figure 7(a) located in central Taiwan area. It is seen that the center of Puli basin is surrounded by mountains. To the north of Puli downtown, there is a highway and a river, and there are several streams at the southern side of Puli. The highway is the main commuting line for labor workers and the river valley is the passage of external air pollutions emitting from western metropolis. The basin geography is a good choice for conducting a pilot study because the quantity of daily inbound and outbound vehicles is not as large as that observed in western metropolis and the citizen living styles are stable, resulting in several frequently seen pollution patterns in the basin. Since 2016, Yin et al. [23] has built an internetwork of 32 low-cost PM$_{2.5}$ sensors in 8×8 km$^2$ area within the Puli basin. The sensors are model G7 PMS7003 that uses a laser beam to illuminate the particles. The scattered light is then analyzed to estimate the particle size and the number of particles. As the residential communities and the business district are near the basin center, more sensors were deployed in the center than the suburban area to monitor the plausible pollutions with a finer resolution. Figure 7(b) shows the deployed sensor sites marked by blue points. We model the studied field by 10×10 grids. The hourly PM$_{2.5}$ concentration of each grid is estimated by applying Gaussian smoothing with the measured intensity of neighboring PM$_{2.5}$ sensors. So for every hour we obtain a PM$_{2.5}$ concentration map image of 10×10 pixels and the estimated PM$_{2.5}$ concentrations in the grids are considered as the gray values of the image. Another version of the map image is produced by converting the PM$_{2.5}$ concentrations to those with 10 air-quality alert levels (see Figure 8) modified from the alert categories defined by Taiwan Environmental Protection Administration (EPA). This alert image is for depicting the concept conceiving the pollution region as an image object. Figure 9 shows an example converting a PM$_{2.5}$ concentration map image (the gray

Figure 6. Framework architecture of the proposed methods.
value is superimposed in the grid for reference) to a corresponding PM$_{2.5}$ alert map image. If we continuously monitor the PM$_{2.5}$ concentrations for 365 straight days, we will produce a time series of $365 \times 24 = 8,760$ PM$_{2.5}$ concentration map images, and another time series of 8,760 PM$_{2.5}$ alert map images. The first time series will be used for pollution episode feature analysis and the second time series will be used for pollution episode retrieval, as will be described in the following sections.

Figure 7. Studied field in this paper. (a) Basin geography of Puli Township. (b) Deployed PM$_{2.5}$ sensors and the 10×10 grid sampling.

Figure 8. 10 air-quality alert levels by reference to the range of PM$_{2.5}$ concentration.

Figure 9. An example of converting a PM$_{2.5}$ concentration map image to a corresponding PM$_{2.5}$ alert map image.

### 3.3.2.3. Pollution spatiotemporal episode retrieval

After converting the PM$_{2.5}$ concentration image to a corresponding PM$_{2.5}$ alert image, we can render the spatial relationship between the pollution alert objects. This will reveal important clues for understanding the spatial context of pollution objects and land objects. For example, we may see a pollution alert level-6 object frequently appears at the southern bank of the river, which indicate a plausible anthropogenic pollution source such as crop burning or garbage combustion. By representing the pollution alert objects and land objects with the 2D Be-strings, the user can sketch the query like...
“show me the hourly alert images in summer where a pollution alert level-6 object appears at the southern bank of the river”. The retrieved result would alleviate the effort to disclose the anthropogenic activities that cause the pollution.

To facilitate this, we need to align the PM$_{2.5}$ alert objects and the land objects into a single image. The PM$_{2.5}$ alert objects can be automatically labeled by the region-growing technique [24]. The minimum bounding rectangle for each alert object is found. For the land objects, they need to be manually labeled. Fortunately, the land objects are seldom changed, we can carefully label these objects one time and use the result for a long period. After we combine the PM$_{2.5}$ alert objects and the land objects into a single image, the corresponding 2D Be-strings of the PM$_{2.5}$ alert image are generated for spatiotemporal retrieval of pollution episodes.

In order to retrieve the interesting pollution episode images in the PM$_{2.5}$ alert time series, a query interface needs to be developed. The Query-by-Sketch (QBS) interface is a broadly adopted scheme in the literature for facilitating the query interface for spatial relationship image retrieval. For example, Giangreco et al. [25] proposed a QBS interface for image retrieval with color sketches. The angular radial partitioning (ARP) for the sketch edges and the color moments are used as the features, and a distance metric is designed for computation of similarity ranking. Wang et al. [26] developed a free-hand sketch interface to graphically portray the spatial ideas of objects for image retrieval. The nearest images stored in the database to the sketch query with similar characteristics are ranked and displayed. In this paper, we developed a QBS interface that is customized to the grid-location and alert-color representation in our time series. Figure 10 shows the layout of our QBS interface and the functions offered by it. The upper half of the layout contains the pallet and the map in grid structures. The pallet offers 10 colors corresponding to the 10 air-quality alert categories with which the user can sketch alert regions and the spatial relationship among them on the map. The map is formatted as 10×10 grid structures with a grid as the minimal unit for an alert region. The lower half of the layout offers a filter function where the user can limit the retrieved episode maps in those satisfying the specified time and weather criteria in the time span and the weather conditions (wind directions, speed, air pressure, temperature, and relative humidity). The filter function is useful when the user intends to deeply exploit the relationship between the retrieved pollution episodes and the seasonal and weather factors. Figure 11 shows a QBS example where the user intends to see if there exist any alert images containing a pollution source along the main road towards the southern bank of the river. So the user sketches a line pollution source coincide with the main road at the southern bank of the river. The center of the pollution source is an alert level-6 object and it is contained in a level-5 object, indicating that the pollution is mitigated as the location is away from the main road.

When the user submits the QBS example query for retrieval, the thumbnail image of the sketch query is shown in the retrieval page for reference (see the upper right of Figure 12) and the 2D Be-strings of the query are automatically generated (see the upper left of Figure 12) as described as follows (also shown in the upper left of Figure 12).

X string: MbMbRb#Me#Re#Rb#Me#Eb#Fb#FeRe#Rb#Ee#Mb#Mb#MeMeRe

Y string: EbMbMbRb#MeRe#RbRb#Me#Fb#ReRe#Mb#Fe#Mb#Ee#Me#Me
As previously noted, the land objects of mountains and rivers have been manually labeled by experts as M and R objects, respectively. The user-sketched level-5 and level-6 alert objects are automatically labeled as E and F objects by the region-growing algorithm. By using the 2D Be-string representation, the spatial relationship between the pollution alert objects and the land objects can be rendered. The similarity score between the query and each image in the PM2.5 alert time series is calculated based on the LCS. The retrieved pollution episodes are then shown in the order of decreasing similarity score to the query (see the lower half of Figure 12). Multiple episodes may share the same similarity score. As seen in the figure, the first seven episodes have the highest similarity score of 0.756756, followed by the next seven episodes which have the similarity score of 0.729729. The last two episodes have the third rank similarity score of 0.716216. The remaining retrieved episodes can be displayed by clicking the “next page” button on the user interface and we present these retrievals in the Supplement material for saving the space. It is noted that the first-rank and the second-rank episodes have similar appearance of alert objects. However, their spatial relationship to the implicit land objects is different. It is seen that the position of the level-6 alert object contained in the first-rank episodes is nearer to the upper side of the image than that in the second-rank episodes, resulting in different spatial relationships to the land objects of mountains and rivers. For the episodes contained...
in the third-rank group, the outer alert object is of level-4, while in the query the outer alert object is of level-5. Another interesting fact is that although multiple episodes share the same similarity score, they may appear at different times and dates. For example, the first-rank retrievals contain the episodes recorded in the morning and evening on different dates in February, March, April, and August. This phenomenon validates our anticipation that some particular pollution episodes frequently occur in a year and the cause for these patterns must be related to local factors which need to be explored. The user can click the retrieved episode of interest (for example, the third retrieved episode in Figure 12) to activate our episode feature detection interface for conducting more focused analyses as will be described in the next section.

### 3.4.2.4. Pollution spatiotemporal episode feature analysis

The spatiotemporal feature detection analysis is designed for automatic detection of various emerging pollution patterns in the time series. There are three commonly seen PM$_2.5$ pollution patterns,
i.e., point source, line source, and region source. The point source is a single pollutant emission spot, such as a combustion furnace. Vehicles plying on roadways are typical examples of pollution line source. Region source has a larger coverage on surface than the point and line sources. For example, the PM$_{2.5}$ purple alert has a large area of serious concentrations because it is usually caused by climate phenomena such as dust storms, cyclones or temperature inversions. We adopt several spatiotemporal masks to detect various pollution patterns. In addition to the classic 2-dimensional convolutional feature detectors (see Section 2.3), we further propose 3-dimensional convolutional filters by including the time domain as the third dimension. A structure of 3×3×3 spatiotemporal filter is illustrated in Fig. 13. It is seen that the center of the filter is aligned with a grid position $(x, y)$ at time $t$ and the filter consists of three masks for time $t - 1$, $t$, and $t + 1$, respectively. There are in total 27 weight values in the 3-dimensional convolutional filter. So the transition of pollutions in both the spatial and time domains can be detected. The 3-dimensional convolutional filter can be generalized to an $n \times m \times k$ mask where $n$ and $m$ are the mask width in the two spatial axes, and $k$ is the mask depth in temporal axis. The value of $n$, $m$ and $k$ are odd numbers to enable us to align the filter center at $M(x, y, t)$, the value of grid $(x, y)$ at time $t$ in the time series maps. We define the convolution operation on $M(x, y, t)$ with an $n \times m \times k$ mask as follows.

\[
R(x, y, t) = \sum_{a=-\frac{k}{2}}^{\frac{k}{2}} \sum_{b=-\frac{m}{2}}^{\frac{m}{2}} \sum_{c=-\frac{n}{2}}^{\frac{n}{2}} w_{a, b, c} M(a, b, c) \tag{3}
\]

Figure 13. The weight values in a 3×3×3 convolutional filter centered at $M(x, y, t)$.

The convolution operation is performed by aligning the filter through the entire image to obtain a response map $R(x, y, t)$. The pollution pattern is declared to be detected at a spatiotemporal location if the absolute response value at that location is higher than a threshold, i.e.,

\[
|R(x, y, t)| \geq \delta \tag{4}
\]

where $\delta$ is the specified feature response threshold.
The automatic episode feature detection is critical when the government agent intends to send technical staffs and instruments to the PM$_{2.5}$ pollution hot-spot in time. Figure 14 shows the example for detecting horizontal and vertical line features of pollutants by clicking the third retrieved episode in Figure 12. The left image shows the original PM$_{2.5}$ concentration map, while the right image is the sum of absolute response maps of vertical and horizontal line features obtained by applying the convolution process. It is seen that there are two major line pollution sources. One is horizontal (at the second row from the top) and is near the exit of the highway, the other is vertical (at the sixth column from the left) and is along the main road connecting the highway exit to downtown. Both line sources are automatically detected by using the $3 \times 3 \times 1$ mask as previously noted. These are typical pollution patterns incurred by rush-hour traffic on a business weekday. The episode feature detection can be continuously performed within a specified time span such as from 5AM to 8PM such that the dynamic changes of spatiotemporal features are displayed for insightful visualization. More complex analyses can be conducted by using appropriate 3-dimensional convolutional filters of an arbitrary size of $n \times m \times k$ to further detect the episode feature differences in the temporal axis. More illustrative examples will be presented in Section 4.

### 4.3. Results

#### 4.3.1. Pollution episode retrieval

In addition to the line pollution source (as shown in Figure 14) emitting from the traffic on the main road connecting the highway to downtown, the pollutants yielded by western metropolis seep into Puli through the northern river valley and the southern streams. The user can visualize this contemplation by sketching a pollution map example as shown in Figure 15. From the left end of Puli, the pollutants drifting through the northern river valley and the southern streams form a particular shape of an alert level-5 object and a cleaner level-4 triangle object to the right end of Puli. When the user submits the sketch example, the 2D Be-strings of the query are automatically generated (as shown in the upper left of Figure 16) and the retrieved most similar images are shown in the decreasing order of their similarity to the query (see the lower half of Figure 16). It is seen that several retrieved images have exactly the same object shapes and spatial relationship among them. Some other retrievals have strip-shape level-4 object rather than triangle objects. This is because the resulting spatial relationship...
between the two alert objects is the same as that in the query. They do have differences in the spatial relationship between the level-4 object and the mountains. From this illustrative QBS example, it is highly possible that the river valley and streams are the main passage of external air pollutions emitting from western metropolis.

![Image](image1.png)

**Figure 15.** The user sketches a QBS query indicating the search intention.

![Image](image2.png)

**Figure 16.** The retrieved most similar episodes for the submitted QBS query in Figure 15.

As a validation of our QBS methodology, we sketch another pollution map (as shown in Figure 17) where the spatial relationship of the two alert objects is opposite to that in the previous QBS example. The retrieved images responding to the query are shown at the bottom of Figure 18. It is seen in the first twelve most similar retrievals, the level-4 object appears at the left end of the image, agreeing with the query intention in the sketch. The remaining four images are retrieved because they have the same objects as in the query but less similar in their mutual spatial relationship. The QBS interface and the 2D Be-string matching are effective in realizing the air pollution image map retrieval in accordance with the user’s intention - in describing the spatial relationship among pollution alert objects.
4.2.3.2. Pollution episode feature detection

The QBS searches for retrievals with most similar spatial object relationship to the query, but without detecting the object shape features and giving no information about the feature temporal changes. Our spatiotemporal feature detection component is designed for this purpose. In practicing the QBS component, if the user sees any retrieval of interest and would like to perform more insightful analyses, he/she can click the particular retrieval and will activate the spatiotemporal feature detection component with the clicked retrieval as the middle of a 24-hour time series (the length of the time window is amendable to the user) to prepare the episode feature detection. Both 2-dimensional and 3-dimensional convolutional filters are applicable to the specified time series.

As shown in the upper half of Figure 19 where the left image is the original PM$_2.5$ concentration map corresponding to the clicked retrieval indicated in the QBS result in Figure 12 and the right image is the snapshot of the feature map for detecting vertical and horizontal line features by applying the 2-dimensional line filters. It is at a morning commuting hour and a line pollution episode is detected at

![Figure 17. The user sketches a QBS query opposite to that in Figure 15.](image)

![Figure 18. The retrieved most similar episodes for the submitted QBS query in Figure 17.](image)
the main street from northern highway exit to Puli downtown. By specifying a length of time window, the video of the paired images (the PM$_{2.5}$ concentration map and the feature map) will be is displayed along the time span in the time series. As shown in the lower half of Figure 19, a nine-hour time window (from 4 AM to 12 AM) is specified and the corresponding video is decomposed into nine pairs of image maps displayed for visualization. The first row shows the consecutive PM$_{2.5}$ concentration maps and the second row displays the real-time detected features. As such, the user can inspect when and where the detected pollution features emerge and when they mitigate. Automatic detection of various emerging pollution patterns in the time series can be also conducted by setting a threshold on the response feature value to produce a binary feature map such that further actions can be activated automatically at the place if its response feature value exceeds the threshold.

Figure 19. The detected horizontal and vertical line features in a specified time window.

Figure 20. The detected edge features in a specified time window.
Figure 20 illustrates the edge feature detection for a pollution episode. A large region pollution source emerges from the downtown. The edge responses start intensifying during the first four hours and reach the peak responses afterward. The edge profile of the region pollution is articulated by the filter. The government agent such as Taiwan EPA can issue a pollution alert in time for the residential area which is affected by the region pollution source.

Figure 21 illustrates the edge features and temporal variations in response by applying both 2- and 3-dimensional filters. An example of applying both 2- and 3-dimensional filters is illustrated in Figure 21. The upper half shows three images which are the original PM$_{2.5}$ concentration map, the feature map produced by the 2-dimensional edge filter, and the feature map obtained by the 3-dimensional filter. A time window of the video is displayed at the lower half of Figure 21 to show the variations in the three types of images. In the first row of PM$_{2.5}$ concentration maps we observe an event where a large region of pollutions emitted at the center of the map and starts to accumulate concentrations quickly in a few hours. In the second row of edge feature maps, the edge outlining the pollution region is clearly articulated and this information is useful for alerting the influenced residents. However, it is not known whether the pollution event is worsening or mitigating in the time span. In the third row of feature maps obtained by the 3-dimensional filter, we see the remarkable concentration variations in the time domain. In the first two hours, though the region pollution has appeared (see the detected edges in the second row), the PM$_{2.5}$ concentration remains constant without being more severe as can be seen in the first two images in the third row most grids have insignificant responses. Since the third hour, the size of the pollution region is not changed, but the third image in the third row indicates that the PM$_{2.5}$ concentration quantity is higher than that in this region observed in previous hours. During the fourth hour and the seventh hour, the PM$_{2.5}$ concentration increases significantly in this region as revealed in the third row where the image becomes darker (having stronger responses) in this period. At the eighth hour, the intensification rate of the pollution becomes slower especially at the northern sites (see the white grids at the north). The pollution event finally stagnates without being worsening at the ninth hour as can be observed in the last image of the third row almost all grids have insignificant responses. From this illustrative example, we see that the 2-dimensional filter is able to depict the locations and
shapes of the detected features, while the 3-dimensional filter can indicate whether the detected pollution gets intensifying, stagnating, or mitigating.

5.4. Conclusions

The purpose of this paper is to propose and develop a framework for air pollution spatiotemporal episode retrieval and feature analysis. The proposed method allows the user of our analysis platform to be a domain expert who is familiar with local terrains, meteorological conditions, and anthropogenic activities, and would like to probe into the reasons why particular pollution episodes are frequently observed in this place and how these pollution episodes are influenced by local terrains, meteorological conditions, and anthropogenic activities.

We propose a QBS interface enabling the user to sketch his/her contemplation of the episode and its spatial relationship to land objects. The user interacts with the QBS interface until an episode of interest is retrieved. Then the user clicks the interesting episode to activate the spatiotemporal feature analysis interface. Various 2-dimensional and 3-dimensional convolutional feature detection filters are offered. By setting a threshold, the feature analysis interface is able to detect when and where the pollution episode emerges, stagnates, and diminishes. The experimental results demonstrate the effectiveness of the proposed methods that traditional methods cannot reach.

for air pollution spatiotemporal analysis rely on probability, statistics, regression, and time series analysis, lacking a viable visualization platform for easy interpretation of the analysis result. Although clustering technique has been employed in the literature for visualizing the partition of homogeneous pollution regions, still many other machine learning approaches have not been explored in this domain.

The advantages of this paper is the advantage of image processing techniques in offering the user an interactive analysis platform for visual spatiotemporal retrieval and feature analysis of air-pollution episodes. The user of our analysis platform could be a domain expert who is familiar with local terrains, meteorological conditions, and anthropogenic activities, and would like to probe into the reasons why particular pollution episodes are frequently observed in this place and how these pollution episodes are influenced by various local factors. Our QBS interface enables the user to sketch his/her contemplation of the episode and its spatial relationship to land objects. The user interacts with the QBS interface until an episode of interest is retrieved. Then the user clicks the interesting episode to activate the spatiotemporal feature analysis interface. Various 2-dimensional and 3-dimensional convolutional feature detection filters are offered. By setting a threshold, the feature analysis interface is able to detect when and where the pollution episode emerges, stagnates, and diminishes.

Use of AI tools declaration

The authors declare that we have not used Artificial Intelligence (AI) tools in the creation of this article.
